8 January 2020

Abstract

The Multiplayer Online Battle Arena (MOBA) game is a popular type for its competition between players. Due to the high complexity, balance is the most important factor to secure a fair competitive environment. The common way to achieve dynamic data balance is by constant updates. The traditional method of finding unbalanced factors in a MOBA game like DOTA2 is mostly based on professional tournaments, which is a small minority of all the games and not real-time. We develop in this paper an evaluation system for the DOTA2 based on big data with clustering analysis, neural networks, and a small-scale data collection as a sample. We then provide an ideal matching system based on the Elo rating system and an evaluation system to encourage players to try more different heroes for a diversified game environment and more data supply, which makes for a virtuous circle within the evaluation system.

1 Introduction

The explosive development of the Internet has brought great convenience to people, and also made leisure and entertainment style much more diversified. Electronic games [10], especially e-sports games, have become an important part of people's lives. With the increasingly diversified social life and the gradual emancipation of people's minds, electronic games are becoming more and more mainstream, especially among young people. As a common entertainment in daily life, the electronic game is a good help for people to eliminate fatigue and reduce the mental pressure of studying and working. Some healthy games can even help children grow up happily in an educational way [3]. Research shows that games have a good effect on the development of the brain, especially in minors.

With the substantial increase in hardware performance and people's desire to pursue better entertainment, various types of high-quality games are coming to people's daily life. Multiplayer Online Battle Arena (MOBA) games [2] are very popular among young people because of their interesting and playful features. The reason why there are so many MOBA game lovers is the competition in all kinds of areas such as operation, strategy, teamwork. The basis of this competitive pleasure lies in its balance.

DOTA (Defense of the Ancient) is the first independent MOBA game. A classic game with a 15-year history, it is still very popular as the second generation DOTA2. Witnessing its enduring popularity, more and more companies have seen the business opportunities, so a batch of similar MOBA games came out, League Of Legends from Riot Games, Heroes of the Storm from the famous Blizzard Entertainment, Heroes of Newerth from S2 Games are all excellent MOBA games. Even though they are not as balanced as DOTA, they still have a large number of players.

Success and failure always exist simultaneously, so not all games are as excellent as the ones mentioned above. In China there are even more MOBA games, but most of them are commonly criticized for their low quality, unbalanced setting, even plagiarism. Game design is actually a process of producing artwork: beside creativity and inspiration, exquisite workmanship is also required. Balance is the workmanship of games, and is even more important in a competitive MOBA game. An imbalanced game cannot guarantee the loyalty of the fans; players will get bored easily if they only have a few options to

win a game. Thus a deep understanding of the balance of the game as well as the way to achieve it are both necessary.

This paper develops a new method for achieving a better implementation of dynamic balance in DOTA2, and then an ideal matching system is designed as an improvement over the original. That is, the main contribution of this paper is a new method to achieve a better implementation of dynamic balance, with small-scale data collection as a sample. As a multiplayer online game, a fair matching system also plays an important role in game balance. Based on DOTA2 original rank/matching system (which uses the same rank system based on Elo ratings as League of Legends), we also design an ideal algorithm for the matching system. Finally we come up with an improvement on the rank/matching system based on the analysis of dynamic data balance.

2 MOBA Games Overview

Mutiplayer Online Battle Arena (MOBA) games are also called Action Real-time Strategy Games (Action RTS, ARTS), or DOTA-like Games. This in turn is all a subclass of Real-time Strategy Games.

In a MOBA game there are no buildings, population, resources, arms training, technology tree, or unit organization, which are all common in traditional RTS games. Players are usually divided into two camps five versus five, and fight for more gold to buy items and for experience to level up; these can both strengthen the players' units. The ultimate goal is to destroy a certain building of the other side. Unlike most traditional hard-core RTS games such as Warcraft III: The Frozen Throne and Star Craft, MOBA game player usually controls one character only called "hero", which has specific abilities and slots to equip with items.

Compared with traditional RTS game, MOBA games are more entertaining, so the difficulty of the operation is designed to be acceptable for most of the average players. Not deliberately requiring any high level of operation and mental strength makes MOBA games more universal, and easier to start. Most MOBA games are also free games, which is another low threshold for a large number of players.

2.1 The Development Path of MOBA Games

In 1998 Blizzard Entertainment released the classic RTS game Star Craft. This was the first time that Blizzard bound a map editor with a game, which allows all the players to edit their own map. Among all custom maps, the one named Aeon of Strife from an unknown player became originator of all MOBA games.

In 2002 "the conscience of the gaming industry" Blizzard Entertainment released the legendary sequel of the Warcraft series named Warcraft III: Reign of Chaos. As before, a map editor was released with the game itself, which threw players once again in the madness of designing custom maps. In a short time, a group of map designer got together and planted the seed of DOTA, the milestone of MOBA games. The warcraft-version Aeon of Strife first came out, followed by Valley of Dissent and Defense of the Ancient. Eventually, DOTA All-Star became the ultimate DOTA map, with continuous updates to fix bugs and adjust balance. This is when MOBA evolved into a real game type.

The fantastic game play attracted countless players in a very short time. Tens of unique heroes, various items, fine operability, imaginative tactics, and of course the constantly improved balance, all these advantages allowed DOTA to sweep the world in a few months. Asia, Europe, South and North America were suddenly full of DOTA players and lovers. At the time Warcraft III including DOTA could only be played on local area networks, so LAN battle platform became another business opportunity. Many such platforms appeared, such as GG (Good Game) and VS.

More and more players gave up on all kind of custom maps such as 3C, RPG (Role-playing game),

and even Warcraft III itself to become DOTA fans. It was also at that time that the huge number of players attracted other game companies, which tried to share this MOBA cake. As a result, some excellent MOBA game including Smite and League Of Legends came out, with great success and huge profit. Based on this success even more MOBA games kept coming out.

Since DOTA came out, countless imitations followed the trend. Of course, most of them got their own features, in one way or another. Though DOTA is classic and balanced, it is just a custom map based on the Warcraft III game engine [11] after all, which is a game from 2002. With the rapid development of information technology, old game engines are destined to be eliminated because of their shortcoming and limitations: There is a 8MB limit for Warcraft III custom maps, which means that one day inevitably no more new elements could be added to DOTA, including new heroes, abilities and items. Low image quality was also becoming intolerable to players. Last but not least, some bugs based on the game engine itself can never be fixed in DOTA. All these problems have restricted the further development of DOTA. At the same time, new MOBA games such as Smite and League Of Legends competed for DOTA players based on their own engines and good publicity, and so kept more and more potential players away from DOTA. This phenomenon seemed to suggest that DOTA was meant to gradually exit the stage of history. In 2008 Icefrog, “the father of DOTA” who kept updating DOTA without any benefits for years, finally decided to take a new step in DOTA’s life, that is, make DOTA2.

In 2009 Icefrog and Valve hit an agreement, starting the development and research work on DOTA2. After two years, DOTA2 came out, and immediately won the praise of players around the world. Based on Source Engine [16], DOTA2 fixed most bugs that would never be fixed in DOTA, with brand new features like skins, watch, matching, voice chat, community, and reports. DOTA2 also became a stand alone game, detached from Warcraft III.

DOTA2 continues to have a large number of players, with a 1.2 million highest number of online players on Steam (the platform of Valve). Also DOTA2 is the leader on professional e-sports game. In 2017, the International 7 was held in Seattle, U.S. with a more than 24 million dollar prize pool. Players who left DOTA returned to DOTA2, which again shows the classic nature and balance of this game. As a high-quality MOBA game, with remarkable gameplay and balance, this paper will take DOTA2 as an analysis template.

Other MOBA games include League Of Legends or LOL developed by Riot Games, Heroes of Newerth (HON) by S2 Games, Smite from Hi-Rez Studios, and Overwatch by Blizzard Entertainment. There are many successful MOBA games; the above are just some representative examples. In general, these games all came from the idea of DOTA, combined with their own creativity such as FPS, and historical or mythological background. No matter the game, the basis of MOBA is the balance, which have the most successful implementation in the DOTA series.

2.2 Properties of DOTA2

DOTA2 is a very complex game. This paper will only introduce the elements that are related to our research.

Every DOTA2 game has generally 10 players, divided into two camps. Every player needs to pick a hero to control at the beginning of the game, resulting in a 5 versus 5 confrontation. The two camps are called Radiant and Dire and have one ancient structure in each of their bases. The bases are located on each side’s high ground, with three lanes to the other side. For each side, there are two barracks (melee and range) and tree defense towers on each lane. Barracks produce three types of “creeps” (melee, range and siege) every 30 seconds, who automatically attack all the enemy units along the lane. Defense towers automatically attack enemies within their range. The strength and number of creeps grow over time. Each side also has two jungles, with some neutral creeps in them. Players control their heroes to kill creeps and enemy heroes to gain gold and experience. Gold can be used to build items strengthening

Figure 1: DOTA2 mini map.

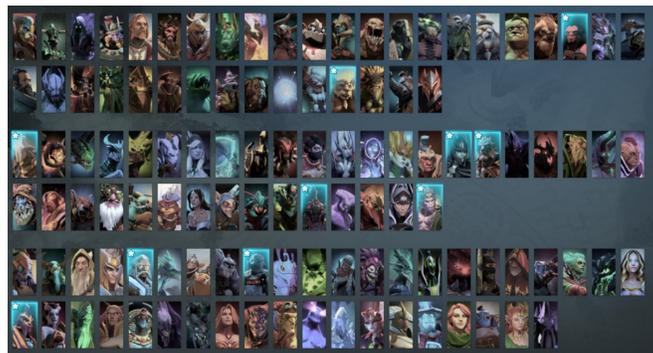

Figure 2: Hero profiles.

heroes. Experience is for leveling up, heroes can get one spell point each level for one of their four abilities (three basic abilities and one ultimate ability which can only be gained on certain levels). The only way to win is to destroy enemy's ancient structure right at the very center of their base. Figure 1 shows the basic structure of the DOTA2 map.

There are 113 different *heroes* (Figure 2) that can be picked by players. Based on their major attributes, each hero is one of the following three types: Strength, Agility and Intelligence. There are more attributes combined in every hero beside these three types (Figure 3), including Armor, Move speed, Attack speed, Magic resistance, Health/Mana points, Damage, four abilities with different cool down and damage types, etc.

Figure 3: Attributes and abilities interface.

Each side has three types of *creeps*: Melee, Range and Siege. Once barracks are pulled down, the enemy's corresponding lane will produce super creeps. If all the six barracks are down, enemy's creeps become mega creeps. Radiant and Dire also have 9 jungle camps each side with neutral creeps (2 of them are ancient neutral creeps), which will refresh every minute if they are killed by players. Some heroes have abilities to summon specific creeps to fight for them.

Items can be bought and built in each side bases' Spring (the resurrection place which can also provide recovery for heroes), the Neutral Shop, and the Side lane shop. Items can be divided into Recovery products (used to restore heroes' health point and mana points), Wards (to provide some vision for a certain time) and other items which can provide some addition on their attributes and specific abilities.

Most heroes have four *abilities*; three are ordinary abilities and one is an ultimate ability. Each ordinary ability can be leveled up with a maximum level 4. The ultimate ability can be leveled up only at hero's level 6, 12 and 18. Every ability has a different effect such as dealing damage, stun, slow the enemy units, or provide beneficial status for the hero and its allies. A talent tree was also added into DOTA2 several patches ago. Each hero can choose their talent at level 10, 15, 20 and 25 to give themselves a unique status or ability bonus.

3 Game Balance Overview

“A game is a series of meaningful choices.” — Sid Meier

The quote above reveals the nature of game balance, namely that every player is supposed to have multiple choices to achieve their goals. Back to MOBA games, the goal is to win the game in the competition. Since there are more than a hundred heroes and items in the game, countless choices like team composition, item choice and combat strategy are made by every player every minute everywhere. Some of them are wise and good, which can lead players to a final victory, others are not. But if only one choice is correct at every crossroad, the game will soon become a meaningless repetition, and so winning the competition becomes gradually boring. This is imbalance. In contrast, a balanced MOBA game is supposed to have bad choices, but there are always several good choices every time, and different sets of options will eventually produce different results. In other words, in a balanced MOBA game you can try everything to win, unlike a robot who follows the same rules all the time.

The fundamental purpose for a player to play a game is to gain pleasure, so the playability of a game decides how long its life will be. In MOBA games balance is even more important for playability than in other types of games. Indeed, nobody would stare at effects, beautiful scenery, or the heroes' panel with many numbers for a long time. Competition is the soul of MOBA games; the intelligence and courage contest determines how much pleasure can every player gain from a game, and all these are based on balance. Without balance, it doesn't even matter if you have more experience or better skill, the one who grabs the “perfect choice” always win the game. This situation could be caused by an unbalanced hero or by a bug in the matching system. In all, balance is always the most important factor for every game designer and developer, from beginning to the end.

“The Battle Arena” reveals competitive attributes, and a large amount of data support is required to achieve fairness. Given that the game is multiplayer, different levels of skills and experience need to be supported as well. A matching system should always balance the strength of both teams to make sure that each side's win rate is as close as possible to 50%. Of course 50% is always the idealized model which can never be achieved. What designers can do is to make it as close as possible to 50%, for there are thousands million choices in every game, from hero pick and item build to ability cast and even every move.

Game data balance is subdivided into static and dynamic balance. Static data balance means that after the design and development, but before the release of the game, all the parameters in the game are

in balance. Dynamic data balance means that after the feedback during internal test and public beta, the production team adjusts data and add new elements through maintenance and update to achieve a better balance. Section 5 will elaborate on the process of achieving data balance in a MOBA game like DOTA2.

3.1 Static Data Balance

Static data balance is the balance that exists in the completed game without any feedback or updates. Ideally, as long as the teams are at the same skill level they will have the same win rate. If so, then the MOBA game is in *static data balance*. Many simple games in real life satisfy this model, such as “Rock, paper, scissors”, where each player has a 50% win rate.

“Rock, paper, scissors” follows an ideal static data balance because of its simple rules: scissors>paper, paper>rock, rock>scissor. When it comes to a MOBA game, thousands of millions of unpredictable factors influence the result every second. However, a good game design blueprint is always highly balanced even before the game’s development, which can also facilitate adjustments after the release to achieve even a more satisfactory a balance. With more and more complicated games coming out, one tries to treat the development of a game as the development of a system because of their similar complexity. A balanced good game should always follow the following three rules in all stages of design and development.

1. *The modularity of game elements*: Every element in the game must only exist for one or a few necessary purposes. If this rule can be followed from the very beginning, designers will not have much trouble fixing or adjusting any problem later on, for adjustment on one part will not affect other parts of the game.

For example, there used to be a “mixed” type of damage in DOTA, which was really a nightmare for the designer Icefrog. This type deals full damage on creeps, but deals both magic and physical damage to hero units, which means hero’s magic resistance and armor must both be considered to calculate the damage reduction. Therefore Icefrog needed to do implement many more calculations when adjusting the “mixed” type of damage to achieve the expected result. In DOTA2 the “mixed” damage is eliminated, and so adjustments became much more convenient.

2. *Coherent design principle*: The coherent design principle [13] is the most important rule for every game designer in the initial design stage. It means that all the elements should be designed based on the overall concept of the game. An element that is independent of the concept of the game will bring about a great deal of imbalance.

One of the most important concept of DOTA is that “every player controls a unique hero unit with corresponding abilities to compete”. An example that does not fit this concept is Arc Warden, with “Tempest Double” as ultimate ability. Once this ability is activated there will be two Arc Wardens with individual health/mana points, status, ability cool down and mobility, so that the player effectively controls two heroes at the same time. Players decided by default not to pick this too strong a hero to play due to the imbalance thus introduced.

3. *Complexity Suppression*: The essence of complexity suppression is to can be summarized as follows “keep things simple and easy to understand. The whole design must be simple and clean, basic concepts should be always followed through all stages to make sure every part is necessary. The more complicated the originally design is, the more difficult later adjustments will be. Making the game concepts easy to understand for players is also every designer’s duty.

Beside the three rules above, *micro-regulation* is an important step to achieve basic static data balance. All types of data require reasonable ranges. The biggest challenge for micro-regulation is how to

Figure 4: DOTA2 updates.

find problems. During this procedure, the modularity of game elements and the coherent design principle are essential. The most effective way for micro-regulation is to do lots of game tests: The testers and the game designers discuss certain conditions, predict the consequences, then verify if the conjecture is correct through actual operation.

3.2 Dynamic Data Balance

Dynamic data balance is the interaction between players and game designers through feedback and adjustments to keep the game in a healthy balance all the time. It actually means that designers fix bugs and do adjustments according to players' reaction and feedback after the game is released. This is still testing in some way, but the group of testers is much larger (every single player in the world). The next update will then adjust the balance (see Figure 4).

Focusing again on DOTA2 as an example, Valve has a dedicated team to accept reports from players around the world in the DOTA2 community. If too many players report a single imbalanced problem (or a bug), analysis and adjustment will be considered for next update. Another important reference is Professional Tournaments. There are around 100 games in a DOTA2 professional tournament [15]. From the behaviour of professional players, most based on the popularity of the heroes and items, Valve analyzes which heroes or items are picked the most and which the least. With the principle "balance every single hero", they will strength as the most unpopular heroes and nerf (weaken) the hottest. For example, in the International 2013 tournament, almost every hero on "Most Ban/Pick" list shown in Figure 5 got a nerf in the next update to weaken their popularity. This idea is simple but effective: in most conditions, the more powerful a hero is, the more popular it will be, especially in professional games. While every DOTA2 tournament consists of around 100 games, with such a limited data collection (Figure 5) only significant imbalance can be identified. It should also be mentioned that professional players are only a very small part of the DOTA2 community, so this method cannot reflect the imbalanced factors comprehensively.

The above methodology makes the evaluation one-sided and not real time (big professional tournaments only happen every 2 to 3 months). This is the main problem we try to address in this paper; a new

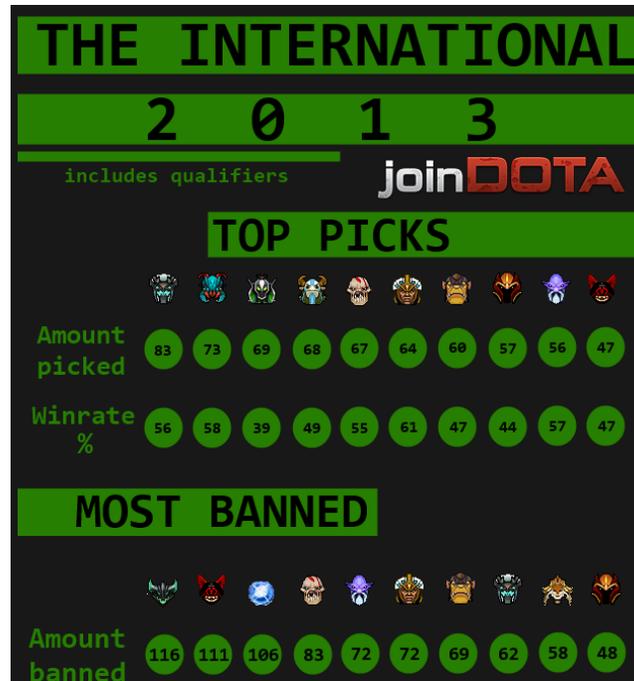

Figure 5: Most Ban/Pick heroes in the international 2013.

method based on data analysis for all players is developed in Section 5.

3.3 Matching System Balance

A player's level depends on experience, personal reaction time, teamwork awareness and physical/mental status. Without a reasonable matching system that can give every player an appropriate evaluation on their level it would be impossible to set up both team to have a similar overall level before the game starts. Fortunately, even if most MOBA games' matching system are not able to judge every player's level every movement, they still have a general judgement for every player according to their performance in a large number of past games. After awhile, the evaluation system can objectively reflect the player's level.

DOTA2 has an excellent matching system with MMR (Match Making Rating) for every single player. In Section 5, through a detailed analysis of DOTA2 matching system, an ideal matching system with improvements will be developed.

4 Further Preliminaries

K-means cluster analysis will be used in this paper to cluster all the heroes into different types according to their data, so that the same type of heroes can be assessed with the same standard afterwards.

Given a set of observations (x_1, x_2, \dots, x_n) , where each observation is a d -dimensional real vector, K-means clustering [8] aims to partition the n observations into $k \leq n$ sets $S = \{S_1, S_2, \dots, S_k\}$ so as to minimize the within-cluster sum of squares or WCSS (i.e., variance). This is accomplished by randomly selecting k cluster centroids μ_j , $1 \leq j \leq k$, determine cluster membership based on the distance from centroids, calculate new centroids by averaging the coordinates of the vectors in the current clusters, and repeat this process until the centroid selection converges.

An artificial neural network [17] consists of numerous simple units connect as a network. There

are several kinds of neural networks, but based on our data processing requirement this paper will use a *BP-neural network* [14]. Such a network will be used to determine the specific weights of each type of data for every type of heroes respectively, for the final complete evaluation system.

The BP-neural network is based on the back-propagation algorithm. It is a multi-level learning network with supervised learning, featuring input and output neurons but also a “hidden” layer of neurons. The learning algorithm adjusts the parameters of the neurons based on the training data. Thus, a BP-neural network converts the input/output problem of a group of samples into a nonlinear optimization problem, which uses a gradient descent algorithm most commonly used in optimization techniques.

4.1 The DOTA2 Matching System

An idealized matching model can be established based on a rank system: Select 10 players with the same rank scores to start a game; once the game is completed, each winner can earn certain scores, while each loser loses the same scores. This model however is difficult to achieve in real life with limited time and players: 5 to 10 minutes would be the maximum matching time for a normal player to tolerate, and finding 10 players with exactly the same scores within this time might be an impossible mission.

DOTA2 therefore did some effective adjustments on its matching system to provide a better experience. While under this system the changes in scores may surprise players after a game, these changes are all reasonable from a statistical point of view.

For example, the most important principle in DOTA2 matching system is that both sides have a similar average score, which has the largest weight in the final matching. If one side has a significantly higher average score than the other side, they will gain less if winning the game, or lose more if they lose the game. The opposite is true for the other side. In this system, the higher-score team also has a higher win rate; if the result goes the other way, the system will reward the lower-score team more and also punish the higher-score team more, as a compensation for the matching system. Language is also an important factor in MOBA games. DOTA2 matching system tries to match all the players who have the same first language based on their setting, or at least the 5 players on same side have the same language.

So far the matching system only cares about matching 10 solo players, yet in most cases 2 to 5 party players start a game as a group. Considering that most people would have different behaviour and game styles with their friends in real life rather than strangers in the game, DOTA2 has two individual rank systems, with “solo” and “party” scores being used in these two modes, respectively.

The Elo Rating System The Elo rating system [7] is a method for calculating the relative skill levels of players in zero-sum games such as chess. The Elo model was originally based on a normal distribution. However, practice shows that the performance of the players is not normally distributed, so the current hierarchical scoring system usually uses the logistic distribution $f(x) = L/(1 + e^{-k(x-x_0)})$, where x_0 is the x -value of the sigmoid’s midpoint, L is the curve’s maximum value, and k the steepness of the curve.

If Player A has a rating of R_A and Player B a rating of R_B , then the formula (using the logistic curve) for the expected score of Player A is $E_A = 1/(1 + 10^{(R_B - R_A)/400})$. Similarly the expected score for Player B is $E_B = 1/(1 + 10^{(R_A - R_B)/400})$. Supposing Player A was expected to score of E_A points but actually scored S_A points, the formula for updating their rating is $R'_A = R_A + K(S_A - E_A)$. The factor K is based on the scoring rules and depends on what is the score unit for each game (10, 50, or even 100). $S_A = 1$ if player won the game, else $S_A = 0$.

In the Elo rating system the new updated rating for a player is only related to his original rating, the outcome of the game (win/lose) and the opponent’s rating before the game, which satisfies the basic ranking/matching system of DOTA2. Players’ behaviour is similar in competitive games. Finally, official description of another MOBA game League of Legends confirms the fact that its rank/match system is

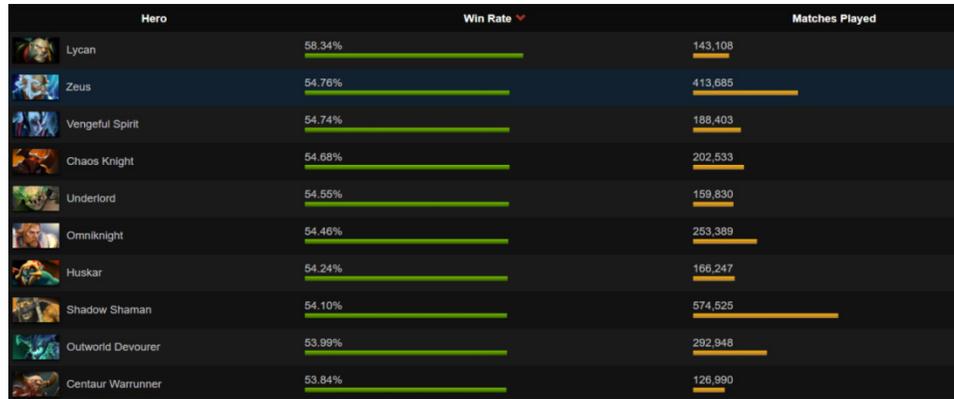

Figure 6: DOTA2 top 10 win rate heroes in very high skill games (January 2018).

Figure 7: DOTA2 top 10 damage dealt heroes in very high skill games (January 2018).

based on Elo ratings [12]. Considering their high level of similarity, we thus assume that DOTA2 follows the Elo rating system in the same way.

5 Balance Implementation in DOTA2

Static data balance is only a concern in the research and design stages of a game. Especially important for a MOBA game like DOTA2 is to keep a guarantee of its dynamic balance by patches and updates. In order to accurately evaluate the balance/ imbalance factors, this paper will establish an evaluation system for Heroes. Inspired by this evaluation system we then introduce an ideal matching system based on the Elo rating system together with some other improvements to achieve a better balance.

5.1 An Evaluation System for the Dynamic Data Balance of Heroes

Since the purpose is to find potential imbalanced factors, win rate (Figure 6) and damage dealt (Figure 7) would be good choices to judge if a hero is too strong [1]. There are 17 different heroes in these figures. Zeus, Huskar and Outworld Devourer appear in both figures. Considering more types of data is needed and will be collected through an API later, but we will only focus on these heroes to simplify data processing.

Then we collected a 10-player sample (random selected from one of the author’s friends list) with the behaviour of these 17 heroes as shown in Figure 8 in all games they have played (ranging from 2 to

Figure 8: Average damage dealt per game using 17 heroes by 10 players (January 2018)

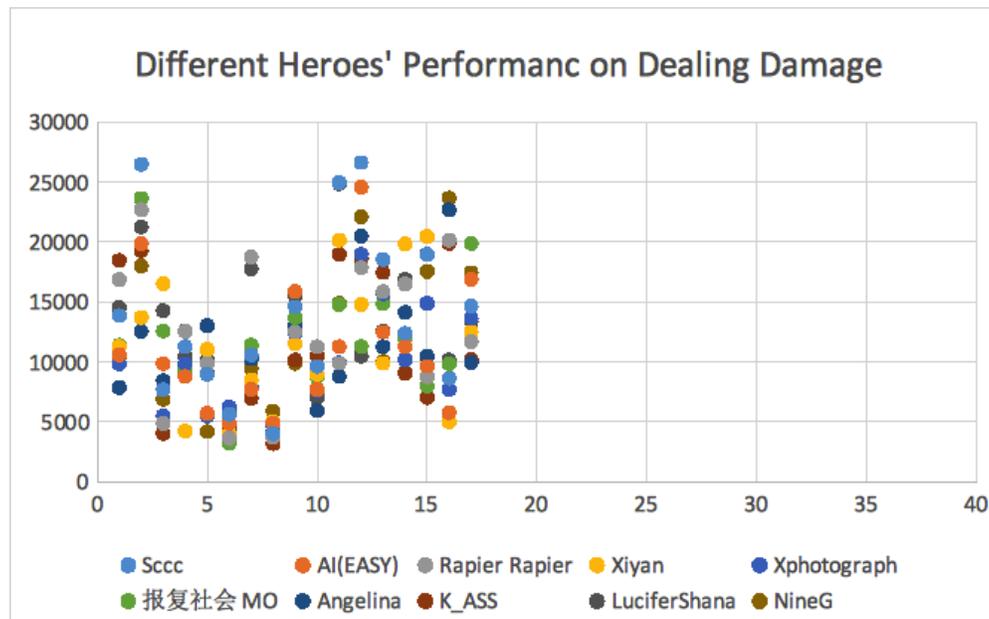

Figure 9: Different heroes' performance on dealing damage.

23 games individually) in January 2018; damage dealt is used as an example in Figure 8.

According to the distribution shown in Figure 9 it is easy to see that different heroes' ability to deal damage differ substantially. Thus damage dealt appears to be an important standard to evaluate whether a specific hero is too strong or not. However there are obviously more factors that must be considered for a complete picture. Different heroes have different positions, attributes and abilities. All these features of various heroes have different effects in every DOTA2 game. For example, some heroes are meant to deal a huge amount of damage; some on the other hand are good at limiting enemy heroes' actions with stuns, slow, silence, etc; some others are supposed to help teammates by healing and take damage from the enemy. Focusing on one or a few specific data is not a wise way to evaluate heroes.

Figure 10 show three different types of heroes: Zeus has a damage-dealing abilities of 4, so that even a bad player can deal a lot of damage with it. Centaur Warrunner, a representative tank, is supposed to take the most damages from enemy in every team fight, and also deals some damage at the same time. Shadow Shaman, usually played as a support, helps cores (damage dealers) have a better environment to farm and stun enemy heroes to let allies have easy kills.

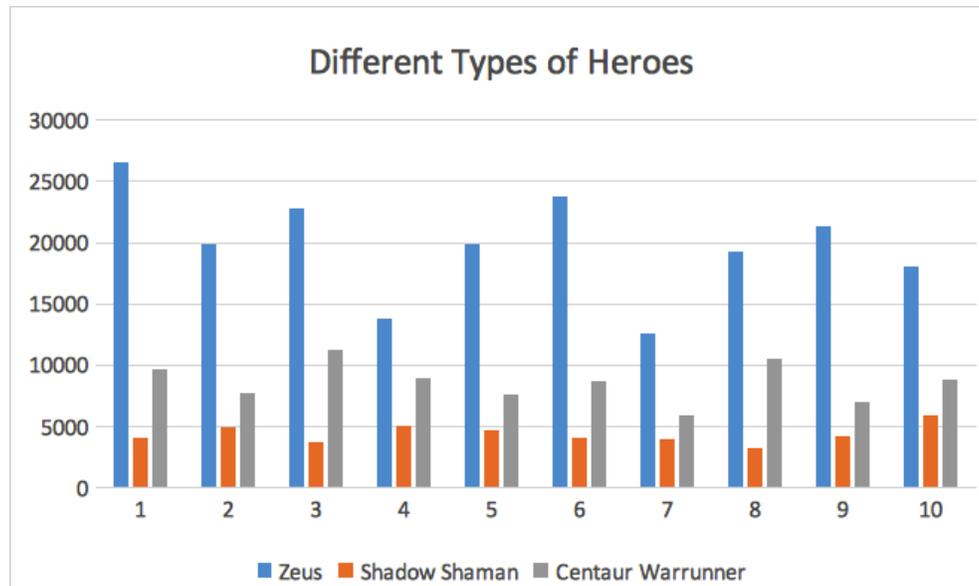

Figure 10: Different types of heroes.

These samples show that the evaluation should be done in a comprehensive way considering all the abilities of a hero. In this aspect, even the data analysis website dotamax.com still have many deficiencies in that it features too few types of data. Fortunately, DOTA2 itself has an application programming interface (API) for its database including every single game's detailed data [5, 18]. From these schemes, many more types can be obtained directly such as "damage taken" or "stun time" for every single game. With all these data, comprehensive analysis becomes possible. The following are the factors that are significant in the assessment of a hero:

1. *Win rate* is the most important factor to evaluate, weight S is given.
2. *Damage dealt* can be divided into two subclasses as Building damage dealt, and Hero damage dealt. Since the only way to win a DOTA2 game is to destroy the enemy's Ancient base, and killing enemy's heroes would lead to an easy push, these two factors are both important for every single game. Weight A is given.
3. *Time of stun and hex*: Stun and hex can totally restrict any of enemy heroes' actions, which will lead to an easy kill. However stun and hex themselves cannot make a killing happen like damage dealt, so they have a lighter weight B .
4. *Time of debuff* includes silence, root, slow and mute. These debuffs can only restrict one of the abilities such as move, attack, using ability or items, so they are even weaker than stun and hex. Weight C is given.
5. *Buff and heal* provide a beneficial effect for allies including speed up and extra damage (buff), and help allies regenerate their health/mana points (heal). These two factors have the same weight C as debuff.
6. *Damage taken* is helpful but it is not necessary all the time. Sometimes having a high capacity to take damage may even promote mistakes. In all this is weaker than all the factors above; weight D is given.

	A	B	C	D
1		Average Damage	Average Stun(s)	Average Healing
2	Lycan	12504.4	22.4	3425.5
3	Zeus	19730.9	42.8	80
4	Vegenful Spirit	9047.7	87.6	194
5	Chaos Knight	9704.9	99	864.2
6	Underlord	8716.2	63.5	1109.6
7	Omniknight	4648.3	18.3	5804.8
8	Huskar	10923.3	8.6	1095.2
9	Shadow Shaman	4340.3	156.4	92
10	Outworld Devourer	12899.3	18.9	0
11	Centaur Warrunner	8594.4	105.2	889.6
12	Tinker	15840.5	39.5	162.5

14	Bristleback	13858.6	12.3	1824.5
15	Sniper	13433.4	8	0
16	Gyrocopter	13461.7	48.8	0
17	Arc Warden	13341.2	22.9	135
18	Ember Spirit	14013.1	9.5	0

Figure 11: Average statistics of 17 heroes.

7. *Support ability* is mainly reflected in purchasing supportive items for the whole team, such as wards to provide vision and dust/sentry for detection. Supportive behaviour is very important in MOBA games including DOTA2; we give the weight B for it.

Obtaining accurate weights requires massive computation and iterative verification based on big data. Our aim is to provide a method rather than complete the calculation. Once the weights are determined we can construct the formula for the assessment of heroes as

$$M = \sum_{i=1}^n W_i \times F_i \quad (1)$$

where F_i represent the normalized average values for the factors listed above, based on the data from all DOTA2 games over a period of time, and W_i are the corresponding weights listed above. M thus becomes the *Balance value*. In a certain period of time (for example a month after the last update is released), if a specific hero has a significantly abnormal balance value (too high or low), it is very likely that the last update has a very imbalanced effect on this hero. A fix may be needed after more tests to decide whether a new update is necessary.

However, based on the general idea outlined above it is easy to see that the “damage dealt” (to heroes or towers) type heroes always have the best assessment since these two data have the highest weights all the time. In practice things are not that simple. Many imbalanced heroes are so because of their different functional abilities, such as long-time stuns and huge amounts of hero healing. The assessment above is therefore not suitable for every unique hero. A better classification is required.

Besides the damage dealt data above, two more data are now considered: Stun Time and Hero Healing (as a representative of Buff). There is no big data directly available for these two on the statistics website. Instead we obtained the other 2 types of game data from the combat summary of the 10 players mentioned earlier, using 17 heroes in January 2018. Figure 11 shows the average statistics for stun time, hero healing, and damage dealing.

We have then performed clustering analysis [9] using Weka.

The first step is to determine the number of clusters. According to the rules of DOTA2, Heroes are divided into two primary roles, known as the Carry and the Support. Carries, which are also called

Final cluster centroids:

Attribute	Full Data (17.0)	Cluster#		
		0 (5.0)	1 (1.0)	2 (11.0)
AverageDamage	11978.4353	8142.3	4340.3	14416.5091
AverageStun	45.5353	74.72	156.4	22.1909
AverageHealing	735.1471	1612.44	92	394.8455

Figure 12: Result of clustering analysis on 17 DOTA2 heroes data.

“cores”, begin each match as weak and vulnerable, but are able to become more powerful later in the game, thus becoming able to “carry” their team to victory. Supports generally lack abilities that deal heavy damage, instead having ones with more functionality and utility that provide assistance for their carries. So basically a Carry is responsible for dealing huge amount of damage, while Supports create better chances for their Carries, eg, by controlling the enemy (stun) or by healing allies. However in our opinion, two classifications are not enough. Some heroes in DOTA2 can deal some damage (maybe not that much though), while offering stun and healing at the same time. Most players called this kind of heroes Functional Cores. We therefore submit that three types called “Carry” “Support” and “Functional Core” are needed.

Figure 12 shows the summary of our clustering analysis. Clusters 0, 1, 2 represent Functional Core, Support, and Carry, respectively. Hence Cluster 1 mainly contributes stun, Cluster 2 mainly contributes damage, and Cluster 0 does pretty well on damage, stun, and healing at the same time. More concretely, the only element in Cluster 1 is Shadow Shaman, which is indeed an excellent support position hero in DOTA2. Vegenful Spirit, Chaos Knight, Underlord, Omiknight and Centaur Warrunner are indeed able to deal some amount of damage and offer healing and stun at the same time. Others are purely damage dealers. The reason there is only one support hero is that the sample was picked as 10 most damage dealing heroes and 7 highest win rate heroes, so the data is supposed to have most elements in Cluster 2 and least elements in Cluster 1, which reflects the real world situation. Notice that determining the type of a hero should be based not only on the three types of data considered here, but also on the other factors discussed earlier. We limit our cluster analysis only on these three data points due to the limited resources allocated to this work. Extending our analysis to more data is however immediate.

Based on the cluster analysis, we refine the weights for our heroes’ abilities in Equation (1) as follows:

1. *Carry heroes*: damage dealt $>$ healing \geq time of stun and hex
2. *Support heroes*: time of stun and hex $>$ damage dealt \geq healing
3. *Functional cores*: the weights of damage dealt, healing and time of stun and hex are almost at the same level.

We used the following principle: Each type of heroes has its specific duty, so the most important capability for a single hero is based on what it is supposed to do (deal damage or support team or limit enemy). The other abilities are not that important compared with its main purpose. This way, the balance of every single hero can be quantified in the same evaluation system. A better balanced update can be completed afterward based on big data on thousands million games rather than only professional tournaments.

Carry	BalanceValue	FunctionalCores	BalanceValue
Lycan	0.305882353	Vegenful Spirit	0.603650768
Zeus	0.760553204	Chaos Knight	0.675028769
Huskar	0.178206232	Underlord	0.478515032
Outworld Devourer	0.107470106	Omniknight	0.3
Tinker	0.471929363	Centaur Warrunner	0.624677433
Spectre	0.473918548		
Bristleback	0.231839052		
Sniper	0.202656888		
Gyrocopter	0.366235384		
Arc Warden	0.175338899		
Ember Spirit	0.188945456		

Figure 13: Rough balance values for carry and functional cores.

Suppose the weight of the 11 Carry heroes are 0.5, 0.3, 0.2 for damage, stun, and heal, respectively, and that these weights are 0.35, 0.35, 0.3 for the 5 Functional Cores. Since the Support cluster contains a single sample, this type will be ignored here. We then normalize our values using a linear function ($y = (x - \min)(\max - \min)$). The Balance values for these two types are then shown in Figure 13.

The Balance value ranges from 0.107 to 0.76. Based on these values all types of heroes can be evaluated at the same level. When there are 113 heroes with all the 7 attributes listed above considered, this range will be smaller and more precise. The ideal model will have a range from 0.4 to 0.6.

Based on the rough estimate above, we then used a BP-neural network to determine the weight for each type. We only consider the Carry heroes in this paper as the type has 11 samples, but the extension for other types is immediate. The inputs are the three types of data namely damage, stun and heal. Each input datum has a neuron (1, 2, 3, respectively) and the output is the evaluation for hero's balance (balanced or not) based on the Balance Value M . The Sigmoid activation function is O (which stands for "balanced"), defined as follows:

$$O = \begin{cases} 0 & \text{for } 0.4 \leq M \leq 0.6 \\ 1 & \text{otherwise} \end{cases}$$

To obtain a complete training set some method of determining the output value O is needed. We propose one of the following two methods:

1. Refer to the previous update; if some heroes were modified, then the data before was unbalanced and the data after modifications is balanced.
2. Wait for the next update; heroes with modifications are assumed to have transitioned from unbalanced to balanced.

The logs for DOTA2 replays are only kept for 30 days, which makes it difficult to collect data from last update (it is also the reason why only the data from January 2018 is collected). We will therefore determine which heroes are balanced and which are not using the following assumption for a rough training of the neural network: we suppose that the heroes who just got modifications in the latest update are balanced, while the others are not. According to this estimate the balanced heroes are Lycan, Ember Spirit, Gyrocopter and Tinker, while the other seven are not balanced.

With the three types of data as input, 3 neurons in the hidden layer and initial weight as 0.5, 0.3, 0.2, after the training with 11 samples, the weights for every neuron are as shown in Figure 14.

Hidden layer neurons	Input neurons			Output neurons
	1	2	3	
1	0.205612	0.102755	0.768041	0.5719874
2	0.672780	0.207483	0.344029	-0.263680
3	0.980589	0.462451	0.016968	0.585587

Figure 14: Weight coefficients between every two neurons.

Data Type	Weight (S)
Damage	0.446598302
Stun	0.240285127
Heal	0.31311657

Figure 15: Weight coefficients of every type of data for carry heroes.

We refer to the neurons using the indices i for input neurons, j for output neurons, and k for neurons in the hidden layer, with $1 \leq i \leq m$, $1 \leq j \leq n$, and $1 \leq k \leq P$. The relations between every 2 neurons are given by the method of Wang and Sun [4]: $r_{ij} = \sum_{k=1}^P W_{ki}(1 - e^{-x})/(1 + e^{-x})$ with $x = w_{jk}$, and $R_{ij} = |(1 - e^{-x})/(1 + e^{-y})|$ with $y = r_{ij}$. W_{ki} is the weight coefficients between the hidden layer neuron k to the input neuron i , and w_{jk} is the weight coefficients between the output neuron j and the hidden layer neuron k . The absolute influence coefficient is then $S_j = R_{ij}/\sum_{i=1}^m R_{ij}$, which is the required weight.

Based on this method and the data collected, the weights for every type of data were calculated as shown in Figure 15. We can establish a relatively complete evaluation system for Carry heroes by plugging in these weights into Equation (1), with $(W_i) = [0.446598302, 0.240285127, 0.31311657]$, and the normalized $F_i = [AverageDamage, AverageStunTime, AverageHeal]^T$. Then a Carry hero is balanced if and only if $0.4 \leq M \leq 0.6$.

It should be emphasized again that to simplify the calculation only three types of data are considered. A complete evaluation system will require all the types of data listed earlier.

The process above assumes that the latest updated heroes are balanced, which is likely an inaccurate method. The ideal accurate method is to always keep all the data for every hero for the latest month. After the new update is released (with the traditional methods mentioned above), we can pick the heroes that were modified and separate them into the old version set and the new version set. These sets can be used for training the BP-neural network, where the old version set is unbalanced and the new version set is balanced. Once data is available for a new version we can retrain the system, making it more accurate. The final (“production”) system should be established after several training sessions with different updates.

In all, the sample experiment described above is based on an inaccurate assumption (because as mentioned logs are only kept for 30 days, which makes it impossible to collect data from other updates), which makes it of reduced utility for validating more heroes. The ideal model requires more and persistent data collection for a long time, covering next several updates. This being said, we believe that our system is both feasible and accurate if it is fed with accurate and complete big data. Our system has the following advantages:

1. Updates no longer rely on the limited data from professional tournaments; instead all player around the world can be part of it.
2. The new game changes (like new heroes and new strategies) can be balanced through the reevaluation of the related heroes in real time; any new training can be finished in a short time, with assessment readily available for the next update.

	Average Damage	Average Stun(s)	Average Healing
Sven	16187.5	29.8	0
Troll Lord	14982.3	13.2	1195.2

Figure 16: Average statistics of 2 heroes.

3. With more training, this evaluation system will become increasingly accurate and stable.

Since the third point requires lots of more data for training and test in the future, we only elaborate the first and second advantages:

While 113 unique heroes seem to be enough, this is not actually true for an energetic MOBA game. In fact, Valve Corporation is still designing and releasing new heroes every year to maintain freshness. Some existing heroes are also reconstructed with brand new abilities, which in effect create another kind of new heroes. New (or reconstructed) heroes can be analyzed and clustered in a short time, in respect to their balance for a quick update, rather than waiting for feedback or data from professional tournaments.

With some modifications on the values of its abilities, the position of a certain hero may change. For example, the Hero Monkey King used to be known as a Support, and Naga Siren as Carry. After an update on their ability values (mostly damage and time of stun), Monkey King became Carry and Naga Siren Support. In this case, new clustering analysis and balance evaluation are necessary, which can also be finished as soon as the data has changed with our evaluation system, in a very short time.

When new strategies appear, there may be some heroes who can take full (and unexpected) advantage of them. For example, there used to be a popular strategy in mid 2014 named the Pushing Strategy. This strategy requires all five heroes as a group and destroys enemy's towers early in the game. Only a few heroes are suitable for this strategy such as Pugna, Nature Prophet and Undying. With increasing popularity and higher win rate than other strategies, all types of data of pushing heroes rose rapidly. If this strategy is too strong in most conditions, then the new Balance value of this hero will go beyond the balanced range (> 0.6). If so, then a nerf on this hero in combination with this strategy must be considered, and can be considered in the next update rather than waiting for the results of the tournaments.

This evaluation system based on big data from daily games all over the world can be more accurate and comprehensive, and a real-time reflection of the dynamic data balance of every single hero. Compared with the relatively mature MOBA game DOTA2, it can work even more effectively on a new one, for which keeping the balance in an ideal range in a short time would be important to seize the players and the market.

Example Suppose that two new heroes are released in an update (since e.g., there were no new heroes released during the last 4 months). We use Sven and Troll Lord as examples, since they are pure damage dealer Carry according to experience.

Figure 17 shows the data in the last 15 days from the 10 players sample. Assume that this is the first 2-weeks worth of data for the two new heroes. With our classification, they are classified as Carry hero. To compare them with others, we use Equation (1) to calculate their Balance value with weight coefficients (W_i) = [0.446598302, 0.240285127, 0.31311657]. The outcome is that the Balance values are 0.356003529 for Sven and 0.293009308 for Troll Lord.

Assuming that the weight coefficients are accurate enough (which will happen with enough training), then we can say that these 2 new heroes are a bit weaker than the average level (< 0.4). Some positive modifications are therefore necessary in the next update. All this analysis can be finished in a short time (2 weeks after the new heroes were released).

5.2 Ideal Matching System Design Based on the Elo Rating System

Inspired by the principle of the DOTA2 matching and rank system and the evaluation system described in the previous section, this part introduces an ideal matching system based on the Elo rating system together with some other improvements to achieve a more comprehensive system, that provides a better balance in support of the MOBA game players' experience. Notice that the DOTA2 matching system is not open-sourced, and so not available. Therefore we start from an ideal matching system based on matching rules.

5.3 An Ideal Matching System

The ideal matching system follows the Elo rating system as follows:

Let $K = 50$ (standard points a player may earn or lose after a DOTA2 game) and $S_A = 1$ (player wins this game) or 0 (player loses this game). Based on DOTA2 rank/matching system, there are two Teams A and B with different average rank scores (R_A and R_B) in the same game, 5 players on each side. With $D = R_B - R_A$, we have $E_A = P(D) = 1/(1 + 10^{D/400})$ and $E_B = P(-D) = 1/(1 + 10^{-D/400})$. For convenience we use the Percentage Expectancy Table [6] provided in the appendix to simplify the calculation process. Notice that sores differences are shown in Table 1 while the median of the difference range is shown in Table 2.

As an example, suppose Team A has an average rank score of 3890, and Team B an average rank of 3700. We have $D = 190$ and so $E_A = 0.75$ and $E_B = 0.25$. Therefore if Team A wins the game then every player in Team A will gain 12.5 points and every player in Team B will lose 12.5 points. On the other hand, if Team A loses the game then every player in Team A will lose 47.5 points and every player in Team B will gain 47.5 points.

Based on the Elo rating system, matching rules can be set up as follows:

1. Both sides have a similar average score.
2. The gap between the players with the highest and the lowest score is small.
3. Both sides have a similar experience that is, a similar number of played games for players on both sides.
4. Scores of highest players on both sides are similar.
5. Both sides have similar number of solo/party players.
6. Complete the matching as fast as possible.

With the above rules in mind, we propose the following process for the ideal matching system. Every match making team is a node, and every match is a queue with maximum 10 players. A team can be a solo player with his solo MMR, or a 2-5 party players with their average party MMR. Then:

1. Once a new node comes in, detect if there is an eligible queue for it (the MMR is in range, there is space available for the node, etc.),
2. If yes, then add the node to the queue with minimal score difference.
3. Otherwise, add this node to a empty queue, with the new matching parameters based on the Elo rating system then wait.
4. Once a new node is added to a queue, check if this queue is full.

5. If yes, then find a sever to start this game and empty the queue, otherwise, keep waiting.
6. Every 30 seconds, check if there are new nodes added into the waiting queue.
7. If yes, then keep waiting.
8. Otherwise, expand the condition to a larger acceptable score difference based on the Elo rating system.
9. Repeat from 7.
10. If a queue has waited for 5 minutes, remove all the nodes, repeat from 1 to 6, and empty the queue.

The corresponding flow chart is shown in Figure 17.

5.4 An Improvement on Scoring Method for the ideal Matching System

The matching system above is based on the DOTA2 rank/matching. The rank system is based on the Elo rating system, which is indeed suitable for most competitive games, in real life as well as in e-sports. However for MOBA games like DOTA2, balance is the most important factor. With 113 different heroes, everyone is supposed to have a seat in this game. The Elo rating system only focuses on the outcome of a game, with no concern about what heroes players use. Also, since the perfect balance in this complicated game can never be achieved, there must be some heroes that are stronger than others, which is also why dynamic data balance is required.

What if within a certain patch, all the players only pick several certain strong heroes to play all the time? In this situation the balance of the game will be destroyed, together with the experience of players. From another point of view, some heroes are meant to be harder to get started than most others; if the designer doesn't encourage players to start with them, then the game will lack variety. In order to encourage players to play different heroes for a diverse environment, we propose an improvement on the scoring method discussed earlier.

First, we introduce a new concept called hero rank. This rank reflects the players' level while playing a certain hero, and is similar to the assessment of heroes in Equation (1). While the former focused on an individual player's level compared to others', the latter concerns an individual hero's balance among all. We establish this rank as follows: $H = (\sum_{i=1}^n K_i \times E_i) / n$. H is the rank score for a certain hero of a player, E_i ranges over the data from all the games with this player using the given hero, including Win rate, Damage dealt, Stun/Slow Time, K/D/A, Damage Taken, etc, K_i are the weights for each type of data, which is the same concepts as the weights in Equation (6) (differences between heroes' types, can truly reflect how important this ability is for a certain hero), and n is the number of games the player has played with the respective hero. The number n is effective only when it is greater than a certain, relatively small but not too small a number (such as 10), to make sure the player is familiar enough to this hero for a precise and stable evaluation. This follows the same rule as the calibration of the DOTA2 rank system.

We then compute the Hero-Pool value $T = (\sum_{i=1}^n H_i \times U_i) / \sum_{i=1}^n U_i$ to evaluate a single player's ability to use different heroes. H_i is the Hero rank for a certain hero, U_i is the number of games this player has played with this certain hero, and n is the number of heroes this player has used.

Notice that even if the total pool is 113 heroes, it is not realistic to suppose that every single player can operate every single hero, so n should be set between 30 and 50, which means that the Hero-Pool value only considers a player's highest top 30 to 50 unique heroes' rank, which encourages players to play as many heroes as they reasonably can.

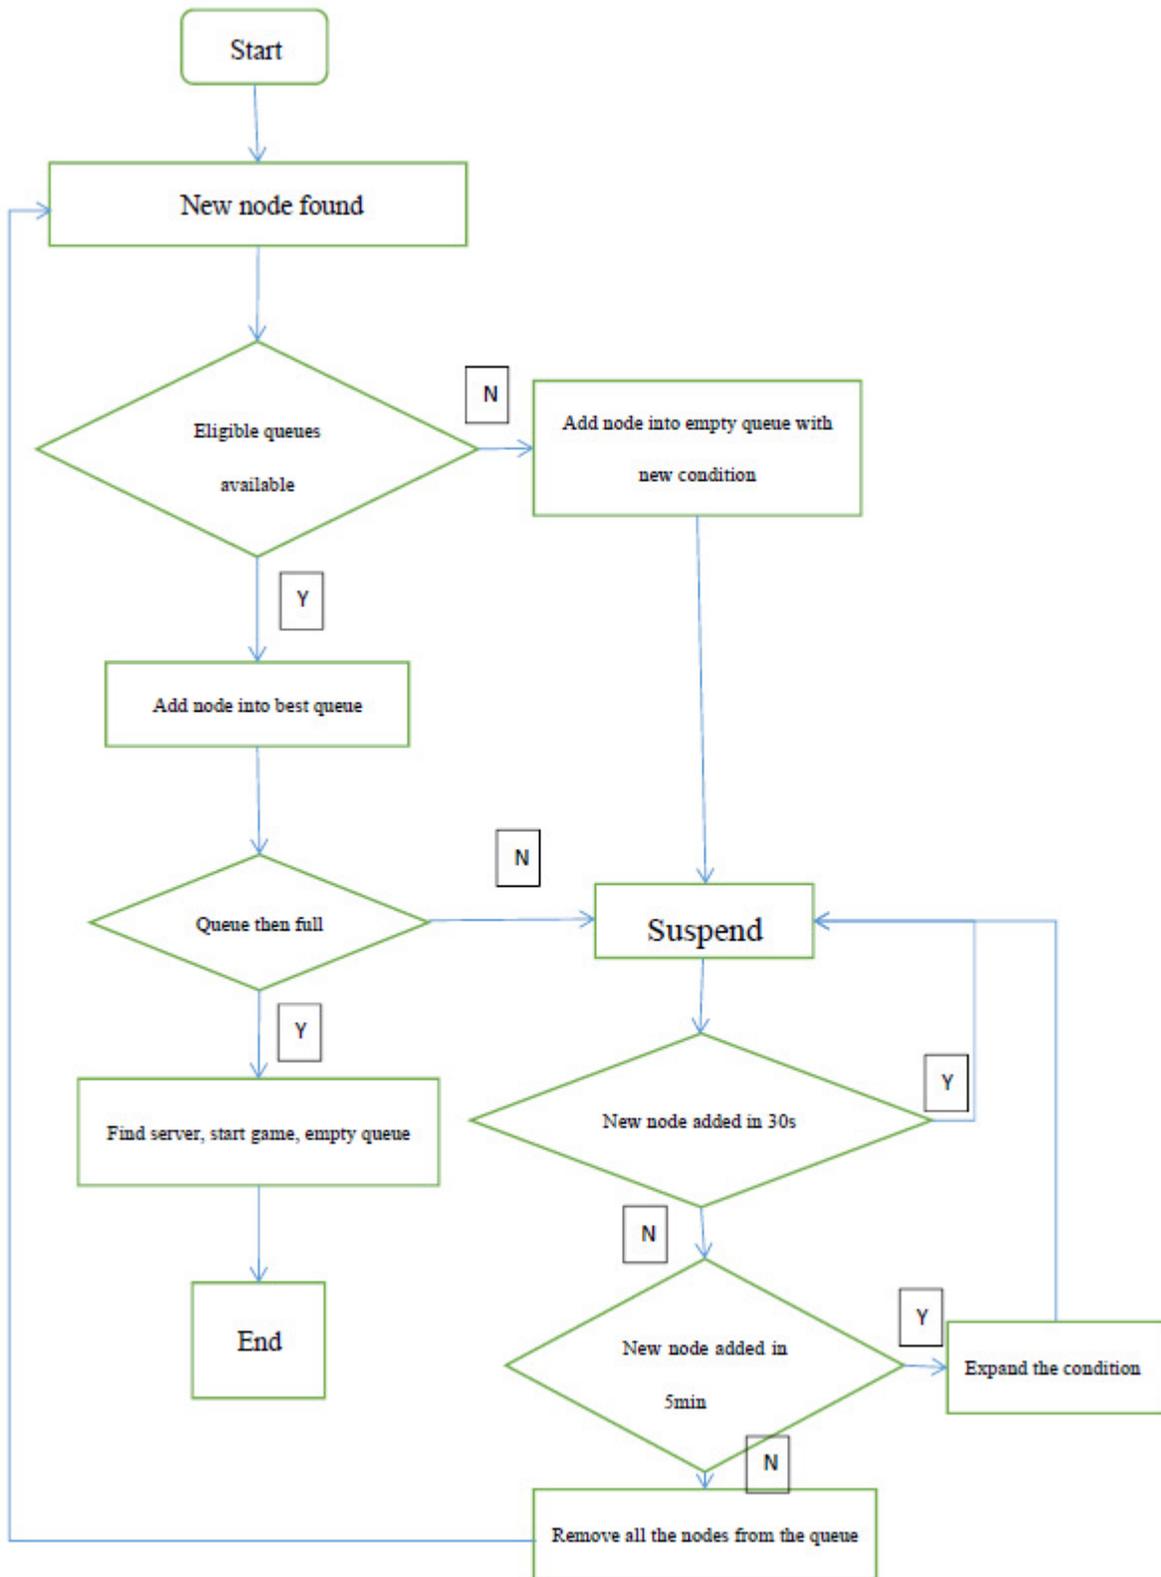

Figure 17: Flow chart for the ideal matching system.

With this value, together with the old formula, we compute the improved final Rank as follows:

$$O = T \times k + S \quad (2)$$

O is the final rank score, S is the old-version rank score based on the Elo rating system, T is the Hero-Pool value, and k is a constant coefficient given by statistical calculations.

With this improvement, the outcome of the game is no longer the only element that affects a players' rank score in the DOTA2 rank system. Players will be encouraged to try more heroes with more combinations in a team. Therefore more heroes will be used in every play, more data will become available, problems and imbalance are easier to find, for an overall better balanced environment. The entertaining value of the game will also increase, with fresh elements for every single player.

The improved matching system developed above is like a bonus in top of the evaluation system (the most important contribution of this paper), for indeed the evaluation system makes it possible to assess players' ability using different heroes based on Equation (1). At the same time, according to statistics some most popular heroes are played 20 times more than the least popular ones, and this gap has a bad influence both on the game environment and on the data analysis of our evaluation system. Therefore the improvement given by Equation (2) on the matching/rank system will directly encourage players to use more heroes for a balanced environment and more data supply for an accurate clustering analysis and evaluation to all the heroes. This is all a virtuous circle.

6 Conclusions

This paper discusses the MOBA type of games, with its development history and game mechanics. We analyzed the importance of game balance and the way to achieve it in MOBA. As an outstanding representative of such games, we focus on DOTA2 and study ways of improving its balance, both on data and rank/matching system. The balance directly determines the diversity, playability and even life of a game, and the traditional method of determining what data needs to be modified in the next patch in DOTA2 basically relies on players' reports and the behaviour in professional tournaments. Thousands of millions players' game data are not considered in this traditional method, which in turn makes it unsuitable for real-time analysis and also not accurate or comprehensive enough.

A new method which consists of data collection, cluster analysis and neural network classification has been developed to quantify the 113 unique heroes in DOTA2, and to measure balance. With original data collected from the DOTA2 API, heroes are clustered into three types based on their features and data. A neural network is then used to determine the weights for every piece of data. A Balance value is then computed as a standard to measure if a certain hero is balanced or not. Based on this further updates can target the unbalanced factors.

Although applied on limited data (30 days worth of logs, only three representative types of data being collected to simplify computing, some inaccurate assumptions), this evaluation is still feasible and effective, especially with more time and data support. This method would also play a better and more important role in newborn MOBA games than in a mature game that is already balanced such as DOTA2.

Based on the Elo rating system, an ideal matching system for DOTA2 is designed, together with an improvement based on the hero evaluation system for a better balanced environment and more data supply. This is the second contribution of this paper.

An immediate continuation of this work would be to investigate how to accurately calculate all the weights from Equation (1) for each type of data. This paper used the strategy to assume that the latest updated heroes are balanced, which diminishes the accuracy of the results of training the neural network. An ideal and accurate method is to always keep all the data for every hero for the last month. After the new update is released (with the traditional methods mentioned above), one can pick the heroes with

modifications, and separate them into two sets (old version set and new version set). We can then train the BP-neural network with the old version set as “unbalanced” and new version set as “balanced”. It should be noted that this method requires more time and data collection. With enough training and our adjustment of the weights (ideally thought 3–4 patches), we believe that this system can become a standard.

This paper only focuses on heroes. Data on items can and should be considered as a factor for data balance as well. Items have the same types of data to heroes’ abilities such as damage, stun, buff, plus price as one more factor to be considered.

In all, the purpose of balance in MOBA is to let every player at similar skill level have a similar chance of winning a game and do so with multiple play choices. This requires between other things a variety of heroes and items, all of them at the same level but with different effects. Only following this rule can both the new MOBA games as well as the relatively developed existing ones offer a great experience.

A Elo Percentage Expectancy Table

Based on the Elo rating and on $D = R_B - R_A$, E_A and E_B can be easily completed from the Percentage Expectancy Table [6] (Table 1). Further score differences can be obtained from Table 2 with the results in Table 1 as the median.

Table 1: P(D) Table according to the Elo percentage expectancy table.

P(D)	D	P(D)	D	P(D)	D	P(D)	D	P(D)	D	P(D)	D
